## Annual Report, 1977-78

### Pacific Radiocological Program

The annual report is an account of work completed during the 1977-78 contract year for two projects - the Amchitka Long Term Effect and Monitoring Project and the Baseline Project. The latter project included the analyses of samples collected in the Central Pacific, including the Marshall Islands and the preparation of reports. The Amchitka project was supported by the Division of Military Applications (114,000) and the Baseline project by the Division of Operational and Environmental Safety (\$50,624).

The report consists of six sections, a summary comment and a report which is attached as an appendix. Appendixes are provided for each section.

1. Amchitka Radiological Long Term Effect Report, January 1977 to December 1977. This is the ninth in a series of progress reports that began in 1973, one year prior to the major event. This report appends the results of analyses of samples collected in September 1977 to the data in last year's report. The results of analyses of the 1977 samples leaves unchanged the conclusions of previous years, namely, that except for small quantities of fission products in the Long Shot mud pits and drainage basin, there are no indications of Amchitka origin in the water, plants, or animals of Amchitka Island. A copy of the report is attached and the report is in the process of publication by the Nevada Operations Office of the U. S. Department of Energy, as report NVO-269-34.

2. The title of the second section of the annual report is, "Results of Plutonium and Gamma Spectrometry of Enewetak Plant, Rat and Soil Samples Collected in March 1977." This is a table of the results of analyses of 306 samples collected and for use by Dr. William B. Jackson and associates of Edwin S. Greiner University in the preparation of a report on the rats of Enewetak Atoll. The analyses of these samples were not a part of the 1977-78 contract. The Laboratory agreed at a meeting at Lawrence Livermore Laboratory in the 1977 to do this work as a replacement of a Spring 1977 trip to the atoll that was cancelled.

3. A report "Radiological Survey of Plants, Animals, and Soil in Micronesia, November 1975" was prepared by Dr. Robert Nelson. Dr. Nelson was a former employee of the Laboratory who was retained as a consultant to prepare this report of the results of analyses of samples he had collected while he was an employee of the Laboratory. The report has been submitted to the Nevada Operations Office of the U. S. Department of Energy and is expected to be published as report NVO-269-35.

4. Dr. Nelson prepared a second report "Radiological Survey of Plants, Animals and Soil of Five Atolls in the Marshall Islands, September-October 1976." He had collected the samples while an employee of the Laboratory. This report has been submitted to the Nevada Operations Office as well as is expected to be published as report NVO-269-36.

5. Although the spring 1977 trip to Bikini was cancelled, some of the samples scheduled for collection at that time were collected in October 1977 when the Laboratory had a field program at Bikini Atoll for another research contract. From that collection 14 coconut samples, 10 pandanus, 4 breadfruit and 2 papaya samples were analyzed for  $^{137}\text{Cs}$  and 23 other samples for  $^{137}\text{Cs}$ ,  $^{239}\text{Pu}$  and  $^{241}\text{Am}$ . Some samples were collected from the same areas in either 1974, 1975 or 1976 and the results of analysis of these samples are presented for the purpose of comparison. Usually the 1977 values were as great as or greater than values for earlier years and hence there is no strong evidence of a decrease in radionuclide concentration with time. For this period this observation indicates a long, or infinite, half-life value for these radionuclides at Bikini Atoll.

6. The quality of our analytical work has been evaluated in two ways - first, by an interlaboratory comparison program and secondly by duplicate or replicate analyses of samples from our own collection. The interlaboratory comparison program, methods of analysis, and the limits of detection are reviewed in section 10.

## ABSTRACT

The final radiocological program began in 1970 and is a continuing program of scientific biological and environmental sampling for radiometric criteria. The results of the program from July 1970 to December 1972, has been given in several previous progress reports from the Laboratory of Radiation Biology, the Pacific Operations Office of the U. S. Navy Institute and development of the program. This report is an account of the program for calendar year 1973.

Results of analyses for samples collected by September 1973, have been reported by Bell and Nelson and Beynon (1973) that summarize the results of analysis of samples collected from 1970 to 1972, and include analyses for (1) various radionuclides in fish, invertebrates, birds, mammals, marine algae, marine invertebrates, benthic invertebrates, and freshwater macrophytes; (2) dissolved  $^{137}\text{Cs}$  in water, birds, and fish; (3)  $^{137}\text{Cs}$  in sediment, marine algae, and fish; and (4)  $^{137}\text{Cs}$  in sediment, freshwater, and biological organisms. Monitoring of background radiation with direct instruments was added to the laboratory's program in 1973, and the results of the laboratory surveys since that date are included in this report.

Conclusions from the results of the recent analyses are a reiteration of the results of Bell and Nelson and Beynon (1973), namely, (1) no new radioisotopes are present; (2) the only biological radionuclides are naturally occurring deuterium  $^2\text{H}$ , tritium  $^3\text{H}$ , and potassium  $^{40}\text{K}$ ; (3) the trace quantities of  $^{137}\text{Cs}$  in fish and invertebrate radionuclides are from world fallout; and (4) a few of the contamination results in some long-lived species previously reported. It is concluded from the results of analysis of samples collected between September 1970 and September 1972, as reported in this and the previous progress reports, that there were no radionuclides of  $^{137}\text{Cs}$  or fission products in the water, plants, or animals of Puget Sound.

FIGURE 1. Location Map

Geological Map of the Cordillera Occidental and Oriental

Figure 1. Collection sites and features shown on map in the Diluvium Area.

FIGURE 6. Collection sites and other important features near the Long Det. Ground, 6-21-1947.

Figure 6. Collection sites and other features related to the Cascadia region.

$^{137}\text{Cs}$  and the appearance of the leading decay correction factor for  $^{137}\text{Zr}$  to the amount of  $^{137}\text{Zr}$  present at the time of sampling gives an estimate of the nuclear power component of  $^{137}\text{Zr}$  present at the time of collection. The detection of  $^{137}\text{Zr}$  in one year has been discussed in Lind et al. (1978).

The CPD of some air pollution data concerning ion ratios for single samples is also presented, covering several 10<sup>3</sup> background standards, and the results are compared with published values. The ratios found for the group of sampling locations are: by single samples are  $^{137}\text{Cs}/^{137}\text{Zr}$  and  $^{137}\text{Cs}/^{137}\text{Ba}$  ranging from 0.0001 to 0.001, and  $^{137}\text{Cs}/^{137}\text{Sr}$  from 0.0001 to 0.001, while for the data from Lind et al. (1978) the ratios are 0.0001 to 0.001, and 0.0001 to 0.001, respectively. The error term for the ratio of the two ratios is about 10% and 10% respectively. The error term for the ratio of the two ratios is about 10% and 10% respectively. The error term for the ratio of the two ratios is about 10% and 10% respectively.

Factors of variation are important since they govern the amount of information that can be derived from a sample. The factors influence the limit of detection, including the type of detector and y-axis, the presence of other radionuclides, the duration of the counting period, the size and geometry of the sample, the geometry of the detector, the sample and detector, and the efficiency of the detector. The factors may vary considerably for various radionuclides and types of samples, but can be summarized by stating that the detection limit and repeatability are defined:

by alpha detection

$$^{238}\text{U} \quad 7.1 \text{ dCi/g of loss}$$

$$^{238}\text{Pu}, ^{239}\text{Pu}, ^{240}\text{Pu}, ^{241}\text{Pu}, ^{241}\text{Am}, ^{241}\text{Fr} \quad 0.41 \text{ } ^\mu\text{Ci/g}$$

$$^{238}\text{U}, ^{232}\text{Th}, ^{232}\text{Pa}, ^{232}\text{Ac}, ^{232}\text{Ra}, ^{232}\text{Rn}, ^{232}\text{Po} \quad 0.17 \text{ } ^\mu\text{Ci/g}$$

by beta detection

$$^{90}\text{Sr} \quad 7.0 \text{ dCi/g of loss}$$

$$^{90}\text{Y} \quad 0.7 \text{ dCi/g of loss}$$

by X-ray detection

$$^{137}\text{Cs} \quad 0.04 \text{ } ^\mu\text{Ci/g of loss}$$

by alpha detection

$$^{238}\text{U}, ^{232}\text{Th}, ^{232}\text{Pa} \quad 0.07 \text{ } ^\mu\text{Ci/g}$$

In addition to the radiocarbon analysis on the biological and environmental samples, environmental radiocarbon surveys are collected every one month in total seven times in August 1977, 1978, 1979, and September 1977 with a 200 liter survey pump, Model 1-440, and a sample pump with a 2 g/l. sampler.

## 2. MATERIALS AND METHODS

During the execution of the 1976 Acetalia radiobiological program, Figure 1 illustrates "The Assessment of the Radioactivity" has been published (Lundgren and Nilsson, ed., 1976a, Chapter 24, "Radiation in the Air, Water and Food" (27 years and later on, 1977) as a survey of the radiobiological stations in Sweden from 1955 to 1976 including the studies reported in the 1976-77 and 1977 annual program reports (Lundgren 1976, 1977) as well as radiobiological projects for the year that began in 1976 and for the next year as illustrated in Table 1. The report described the projects and methods used also for the Finnish radiobiological projects with special emphasis on the year 1977. Other chapters of the book may be of interest in connection with the Finnish environmental based upon extensive studies by many authors (1977).

The samples collected in September 1977 were of the same type and from the same locations as in previous years and included biological, food, and species, water, soil, air, and some terrestrial, terrestrial, and marine environments. The only changes in the 1977 criteria of sample collection and methods were as follows:

1. A water sample was collected from Lake Lene on the coast of Åre and it is used for such in the gross spectra analysis.
2. Water samples from Gustavs and Grampas and Sand Track Cove (up and down stream from the dam) were collected for gross spectra and <sup>14</sup>C analyses, whereas only samples from Gustavs were collected in previous years.
3. The sampling program which is limited to one collection a year in previous years, was supplemented by collection of foodstuffs and water from Väster and Grampas, results and information from the radio lab area in the spring and part of 1977 by staff members of the U. S. Fish and Wildlife Service.

Most of the results were analyzed by gross spectrometry for both alpha and beta radiation and measured by a 4π efficiency corrected counter and analyzed for tritium, <sup>14</sup>C and <sup>3</sup>H by means of 20%, 20% efficiency of radiological analysis are presented in Tables 1 to 10.

\*The assistance of Jarmo Lehty, Meri Elton, and others (Acetalia and other radiobiology (B-01618)) of the Academy funded environmental monitoring program is gratefully acknowledged.

The results of parts spectroscopic analysis for three years of biological samples collected in the Columbia River are given in tables 3 to 5. The results were for mainly (a) fish, (b) bivalves (oyster, clam), and (c) seaweed (rockweed, eelgrass, green algae) with filamentous algae. Samples were collected at 14 sampling stations but only Longview's was present in all biological investigations of the Columbia River and the values for it are used to illustrate a general trend. The values for the Columbia River are generally one to three times the values for the Columbia River in the "year of collection" effect when peak years in 1970-71, 1977, and 1978.

In the Columbia River from the "year of collection" effect, the values for the amount of plutonium 239 (Pu-239) plus plutonium 240 (Pu-240) in 100 grams of fish, shellfish, seaweed, and algae are given with the amount of Pu-239 plus Pu-240 in 100 grams of sediment from the Columbia River and other rivers. Details of sampling and determination of plutonium in biological samples are given in section 7.1 and are also presented in Figure 7.

The variables in Figure 7 were selected by the following criteria: (1) and (2) are indicators of plutonium in drainage basins and of the amount of plutonium present in the Columbia River. Pu-239 plus Pu-240 was selected as an overall indicator because of its greater mobility and abundance in the Columbia River. The Columbia River samples are compared to samples from other rivers and to the sediment in the Columbia River. The Pu-239 plus Pu-240 values are compared to the Pu-239 plus Pu-240 values because the Pu-239 plus Pu-240 values are generally higher and more variable in the Columbia River. The results of one year of the Columbia River survey (1978) and the results of previous and/or other surveys (1970-71) were presented by Figure 7(1978). The Columbia River samples were collected in 1978 and it should be noted by Figure 7(1978) that the results of one year have been treated by a novel averaging scheme. Also, the Columbia River samples were reported in terms of wet weight and by this weight the Pu-239 plus Pu-240 values were calculated from the wet weight dry weight ratio of Pu-239 plus Pu-240 determined from the dry elements of the samples in 1978. The amount of plutonium in the Columbia River is determined by the Pu-239 plus Pu-240 in 100 grams of Figure 7 as other evidence for the following concepts: (1) the amount of plutonium in the Columbia River varies and increases; (2) the amount of plutonium in the Columbia River increases because of the collection of Pu-239 plus Pu-240 in 1970-71, 1977, and 1978; and (3) the collection and measurement system by Pu-239 plus Pu-240 in 1978 is better than the amount of plutonium in the Columbia River.

For cases (1) and (2) above, the overall conclusion is that the amount of plutonium in the Columbia River is generally increasing from the 1970-71 collection of samples. Another method of determining the amount of plutonium in the Columbia River is to determine the amount of plutonium in the Columbia River by the presence of plutonium in the Columbia River. The amount of plutonium in the Columbia River can be determined from the ratio of plutonium in the Columbia River to the amount of plutonium in the Columbia River. The amount of plutonium in the Columbia River can be determined from the ratio of plutonium in the Columbia River to the amount of plutonium in the Columbia River. However, the amount of plutonium in the Columbia River is not

The curves in the graph show the approximate peak wavelength of the radiation emitted by the source as a function of the temperature. The curves are labeled with numbers 1 through 50, corresponding to the temperatures listed in the table below. The curves show a general upward trend in peak wavelength as the temperature increases, with some fluctuations. The vertical dashed line is drawn at approximately x=1055.

$^{137}\text{Cs}$  (66 and 50 days respectively) as the dominant fission product. Radioactivity in the sediments from above radiocesium are of recent origin from the local nuclear fallout from the Aomori (Bokuken 1971) and from the world fallout.

Here we focus on strontium isotopes from the radiocesium data. The  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio was found to be relatively low and constant in the samples related to the fallout. The sediment on Anzaike Island. However, as shown in Table 3, the November 1977 values for the radiocesium from the lake are greater than the radiocesium from the sediments from the Midland area. Although these lakes contained radiocesium, it does not mean that the radiocesium from the Fukushima nuclear power plant is not present in the lakes. From the low radiocesium activity of the November 1977 samples, it is clear that the radiocesium from the Fukushima nuclear power plant was not yet present in the lakes. The  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of the lake samples from the Midland area (November 1977) was 0.7100 and the radiocesium activity was 0.1000 (Bokuken 1971). The radiocesium activity of each sample was statistically determined as being lower than the radiocesium activity of the lake water sampled in November 1977 (0.1000) (Table 3). The mean values, and one standard deviation, for these radiocesium samples from the November 1977 Midland and Bokuken areas are 0.1000 and 0.1000, respectively. In determining the significance of the data differences, the  $F$ -test was applied and the conclusion was that the differences were not statistically significant. Hence, even though the differences were two or three fold, the differences were not statistically significant because of the uncertainty of the error term and the limited number of samples.

Isotopic data values for Kamenets are given in Table 4. For radiocesium, Table 4 and the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio are similar to those from the Midland and Anzaike lakes, indicating that the radiocesium from the Fukushima nuclear power plant is not yet present in the lakes. The radiocesium values for the Midland, Anzaike, and Kamenets are similar. The locations are all in Japan. For the collection and preservation of fallout radiocesium, the same methods and procedures were used for the November 1977 samples. The mean values for  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{137}\text{Cs}$  are similar to those for the Midland and Anzaike lakes.

In spite of the higher radiocesium (Table 7) and lower  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios present, and of lower concentrations for 1977 and 1978, other years, the lake water also has vegetation types, Midland, Anzaike, and Kamenets. The radiocesium activity in the lake water is  $^{137}\text{Cs}$  was present in concentrations that were not statistically different from the radiocesium activity of the lake water. The mean values for  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{137}\text{Cs}$  are similar to those for the Midland and Anzaike lakes.

Isotopic radiocesium values for the Midland area, a marine environment, in terms of  $^{87}\text{Sr}/^{86}\text{Sr}$  of the samples, as given in Table 4, were 0.7100 and ranged from 0.7100 to 0.7100 for the different fission products.

Radioactively occurring  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$  were detected in the two radiocesium samples from Kamenets in 1977 (Table 8-11). The radiocesium activity in 1977 was 0.1000. Bokuken (1971) reported that  $^{137}\text{Cs}$  was detectable in five samples from the Midland area with a  $^{137}\text{Cs}$  activity of 0.1000.

1977, but in 1978 was the predominant radionuclide in all fish samples for all years and for the 1978 fish sample. In contrast, cesium-137 was more abundant than  $^{137}\text{Cs}$ .

Concentrations of  $^{137}\text{Cs}$  in fish from the production areas and the receiving streams in particular varied over the years (Table 17) and, in fact, the 1978 values were significantly higher than the 1976 values. The values for both radionuclides in the 1977 fish samples fell within the range of values for other years.

The samples analyzed for  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$  and the names of lake and stream (Table 18) in the production area were 1977 and 1978. In contrast, only one sample of 1977 fish was taken from Lake Superior during the period, but during the 1978 period fish samples were collected from Lake Superior. The values were slightly higher than for other years for some samples in certain years. Soil samples were collected in 1976, 1977, and 1978. Only one sample for  $^{137}\text{Cs}$  was collected from the point of deposition and this value was 0.04  $\mu\text{Ci/g}$  of dry sample. Soil samples were also collected from the receiving streams. The soil samples were collected at the Long Point and in the Long Point Area and the soil samples for the Long Point and the Long Point Area were collected in certain years: 1976, 1977, 1978, 1979, 1980, and 1981. There were no significant differences in radioactivity values in either year or in either area. The peaks resulting from the radionuclides observed in the soil were  $^{137}\text{Cs}$ ,  $^{134}\text{Cs}$ , and  $^{135}\text{Cs}$  but the concentration in the samples was less than 1  $\mu\text{Ci/g}$  of dry sample. Significant peaks in levels of  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$  were seen in soil samples collected in Washington State during 1977 and 1978 (Robison and Seaman, 1978).

Environmental samples have been collected for gamma spectrometry in 1976, 1977 and 1978. Long Point Lake, Long Point Area, and the Long Point Area were sampled in 1977 and the additional sites of Long Point Area, Long Point, and Sand Beach were sampled. In addition, soil samples were collected for gamma spectrometry in 1977. The results will be analyzed in the receiving stream on completion of 1978 sampling. The most abundant gamma emitting radionuclides in the 1977 soil water samples were  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$ . The long lived  $^{134}\text{Cs}$  has a half life of 2.06 years and the values for  $^{134}\text{Cs}$  were 0.04  $\mu\text{Ci/g}$  and 0.02  $\mu\text{Ci/g}$  respectively. These two radionuclides were present in the November 1977 water sample but at concentrations an order of magnitude lower than the values for the Long Point Area samples. The  $^{137}\text{Cs}$  half life was the same as  $^{134}\text{Cs}$  and  $^{134}\text{Cs}$  was observed in the 1977 soil water in the Long Point and Long Point Area. It would be expected to be present there in the soil samples because of direct deposition from the lake in 1977 and  $^{137}\text{Cs}$  observed in the 1977 water and soil is relatively short lived because of the short half life of  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$  (6.6 and 2.06 years, respectively) and, hence, the principal nuclide to be water soluble. Other significant observations from the collection of these samples is that the radioactivity in samples from the Long Point Area in 1977 was within the range of values for samples from other locations.

of *Aspilota* females sampled exclusively in the June and August 1977 collections. The values for  $\bar{L}$  in continental USA (averaging 2.7) are slightly above those reported for  $\bar{L}$  values. In water samples, the mean  $\bar{L}$  value was not verified by the 1977 data. However, in the previous year, the values for  $\bar{L}$  in low levels from the same sites were similar to the general  $\bar{L}$  values reported here. In comparison with the other areas, when the  $\bar{L}$  values for a given site were related to  $\bar{L}$  values in the same site with the same year, the collected samples of *A. nitida* in the local areas of biological samples in continental USA are related to the general  $\bar{L}$  values of the population of *A. nitida* in the same area of the previous year.

Some (1971, 1976, and 1977) authors (1971, 1976) found that species of *A. nitida* which were analyzed for  $\bar{L}$  values and the presence of parasitoid eggs were present in the soil. The general conclusion was that the  $\bar{L}$  values in the soil were not related to the  $\bar{L}$  values in the water samples. The  $\bar{L}$  values in the soil were compared with the  $\bar{L}$  values of water samples from the Atlantic (1971, 1976, 1977), California (1976) (King et al., 1977), and Washington (1976) (1976) and were found to be higher, i.e., some of the *A. nitida*  $\bar{L}$  values were slightly more than 10% higher than the values for the same areas (1971 and 1976) (1977). For this reason, the source of  $\bar{L}$  values of *A. nitida* is believed to be the same as for other areas of the world (1971).

A biological radiation survey program which detects nuclear defects is called this survey "an/cm" was initiated in 1974 and the results of the survey for 1977 and the three previous years are presented in Table 2. The overall background level of  $\bar{L}$  for *A. nitida* in the background was the same as for the other areas (1971) per cent, although several areas of biological samples generally reflect the results on the  $\bar{L}$  values of the *A. nitida* per cent. The survey areas, including for all areas of *A. nitida* and  $\bar{L}$  were water samples. Therefore, the instrument which is used for measuring the  $\bar{L}$  values of *A. nitida* was similar to the changes in background radiation.

#### 4. SUMMARY AND CONCLUSIONS

The objective of the program is to determine the extent of radiation contamination of *Aspilota* around. The objective is achieved primarily by the collection and identification of a large number of biological and radiological samples. The survey background radiation program is the same as the background of the other areas, and the background level of the *A. nitida* per cent is similar to the other areas. The results of analysis of the  $\bar{L}$  values collected in November 1977 and the background radiation program are that  $\bar{L}$  values for the same collection as in previous years, and the  $\bar{L}$  values are evidence that the background contamination of *Aspilota* is not higher than would be expected based on factors except for a slight contribution of the background  $\bar{L}$  values.

Following are summary observations from various other conclusions as made in reports by HPHH and outside consultant firms of Analytic Island and others in 1976, with the exception of two from reports from the Town Staff of HPHH and one from a report by an outside consultant.

1. Levels of total radionuclides,  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$ , above the level of background radionuclides are negligible.
2. Some fission products, fission radionuclides, and parent products have been detected in samples collected from the vicinity of coastline in a few piles of dry samples.
3. Values for  $^{137}\text{Cs}$  are  $^{134}\text{Cs}$  in various areas and piles from Analytic Island and the Columbia River were similar in magnitude and peaks of abundance.
4. Peaks of abundance of fission products radionuclides occurred in 1970-71, 1971 and 1972 and include major fission products of fission.
5. Two fission products, where  $^{137}\text{Cs}$ ,  $^{134}\text{Cs}$  and  $^{135}\text{Cs}$  are the dominant fission radionuclides in the samples and their  $^{137}\text{Cs}/^{134}\text{Cs}$  ratio was much more recent than the last fission product detection.
6. The radiological level of fission radionuclides, generally, was greater in dry water than for water organisms.
7. There has been no increase in the  $^{137}\text{Cs}/^{134}\text{Cs}$  or  $^{137}\text{Cs}/^{135}\text{Cs}$  ratio in fission radionuclides in samples collected in the vicinity of coastline from underground sites.
8. The background can also be very high, depending on the amount of the town limits of detection for the instrument.
9. The laboratory detection mechanism system for the radiological analysis of the samples was very live in well protected areas in the vicinity and especially in Columbia River in the vicinity of the town.
10. The results of analyses of the 1977 samples completely confirm the results of analyses of samples collected previously and do not reveal any unexpected information.

1951	Jan	15	10:00	Station 100	30.9	10.2	0.1	30.4 - 32.1

The above table shows the estimated mean values for the mean of the logarithm of the number of bacteria at 100 different stations during the month of January, 1951. The values are given in the column headed "Mean Value". The standard deviation and standard error are given in the columns headed "Standard Deviation" and "Standard Error", respectively. The confidence interval is given in the column headed "Confidence Interval".

Table 11

Estimated 40-year Critical Load for the 60-day July Number as derived at 10000hPa (1000hPa)

Year	Location	July Number	radiocesium (Bq/L)	95% CL	99% CL
1970	Deep Cove	2/1	15 ± 0.3	0.1	0.1
1971	Deep Cove	3/1	16 ± 1.0	0.7	0.7
1972	Deep Cove	3/1	16 ± 0.6	0.3	0.3
1973	Deep Cove	5/1.3	11 ± 1.7	0.1	0.1
1974	Deep Cove	12/3.6	12 ± 4.7	0.1	0.1
1975	Cloverton Lake Outlet	1/1	14 ± 0.5	0.1	0.1
1976	Deep Cove	1/1	13 ± 0.7	0.1	0.1
1977	Deep Cove	1/1	15 ± 1.6	0.3	0.3
1978	Cloverton Lake Outlet	1/1	15 ± 2.5	0.3	0.3
1979	Deep Cove	1/1	12 ± 2.1	0.07	0.07
1980	Deep Cove	1/1	16 ± 7.9	0.1	0.1

radiocesium values for a single sample ( $n = 1$ ) are a simple count of the number of alpha particles registered, converted to an average radiocesium value. For more than one sample, the mean value and standard deviation are used to calculate average values.

a) Number of samples/total number of samples (e.g. 2/3 samples).

b) Location

c) Deep Cove, Irving River, Irving River, Irving River, Irving River

d) Deep Cove, Camille Lake, Deep Cove

e) Deep Cove, Camille Lake, Irving River, Deep Cove, Cloverton Outlet

Table 17

Peterson's  $\alpha$  and  $\beta$  for 1970-1972 in Lake Umbagog  
collected at 10 different sites

Date	Collection Location	Volume (liters)	Number of fish	Sample from 100 L of water	
				$\alpha$	$\beta$
1970	South Side	1 liter	1	---	---
1970-71	Castle	Yankee	1	13 ± 1.2	1.6 ± 0.1
1970-71	South Side	Harbor	6	11 ± 0.5	1.2 ± 0.1
1970-71	Castle	"	3	11 ± 1.6	0.75 ± 0.04
1971	Castle	"	3	11 ± 0.8	0.58 ± 0.03
May 71	Castle	"	2	11 ± 1.2	0.67 ± 0.03
Aug 71	Castle	"	4	14 ± 1.5	0.90 ± 0.02
Aug 71	Castle	"	7	16 ± 2	3.4 ± 0.1
Aug 71	North Side	"	2	11 ± 2	1.6 ± 0.1
Aug 71	Wharf Area	"	2	2 ± 2	1.6 ± 0.1
Aug 71	Castle	"	6	12 ± 0.5	1.7 ± 0.05
Aug 71	Wharf/Long Pond	"	2	10 ± 4.1	0.9
Aug 71	Wharf Area	"	2	10 ± 0.6	1.5 ± 0.05
Aug 71	North Side	"	1	5.0 ± 0.6	0.75 ± 0.03
Aug 71	Castle	"	6	11 ± 2.5	2.1 ± 0.05
Aug 71	Long Pond	"	6	0.6 ± 1.0	0.27 ± 0.03
Aug 71	Wharf Area	"	3	12 ± 2.3	0.69 ± 0.03

a)  $\alpha$  and  $\beta$  for amount of fish in sample collected from 100 L of water. Values are given as mean  $\pm$  1 standard deviation of 100 L water with similar sample counts.  $\beta$  is given as mean  $\pm$  1 SD collected from 100 L of water from a single count.  $\alpha$  and  $\beta$  are given as mean  $\pm$  1 SD for 100 L of water from 100 water samples.  $\alpha$  and  $\beta$  are given as mean  $\pm$  1 SD for 100 L of water.  $\alpha$  and  $\beta$  are given as mean  $\pm$  1 SD for 100 L of water.

b)  $\alpha$  and  $\beta$  are given as

c)  $\alpha$  and  $\beta$  are given as mean  $\pm$  1 SD for 100 L of water.  $\alpha$  and  $\beta$  are given as mean  $\pm$  1 SD for 100 L of water.

Table 10. 9. A comparison of the chemical and physical and Analytical Survey Data for the 1970's and 1977's at the 1970's and 1977's sites.

Location	n <sup>a</sup>	Collection Location	Sample Type	Mean <sup>b</sup>	Stdev <sup>b</sup>
1970 <sup>c</sup>	2	Grass/Straw/Tree	Grass/Tree	1.6	0.4
1977 <sup>d</sup>	2	"	"	5.8	0.4
1970 <sup>e</sup>	"	"	"	1.9	0.4
1977 <sup>f</sup>	"	"	"	0.8	0.9
1970 <sup>g</sup>	"	"	"	4.1	0.4
1977 <sup>h</sup>	"	"	"	2.0	0.4
1970 <sup>i</sup>	4	Grass/Straw <sup>h</sup>	Grass/Tree	1.8	0.9

1970 <sup>ae</sup>	3	"	"	0.1	0.4
1977 <sup>af</sup>	2	"	"	0.0	0.4

- a) Leaf-bare sample obtained from 2 to 4 x 100 liter v.
- b) Radiocesium values for 1970's samples (n = 2), collected before May 1970 and a repeated count of the same location shortly afterwards, and 1977's samples for 1977, 1970, and 1977 values are cross-sample counts. The radiocesium value for more than one sample is the mean of one or more collection of same leaf-bare sample values. For 1970 and 1977, a cross-sample count for repeat counts only and, for 1977, an additional cross-sample count of same sample. The maximum effect of these errors on radiocesium values is likely of the order of about 0.6 to 0.7 dpm/g for the (19), for the plumtree (19) and grass/Tree sites (30a).

#### Procedures

- a) Rainwater Data for 1970's samples from 1970's, 1977's, 1970's and 1977's (1970's, 1977's, 1970's, 1977's)
- b) Rainwater Data for 1970's, 1977's, 1970's, 1977's, 1970's, 1977's

Radioactivity Measurements in Sand and Soil Collected at Accident Site

These data were obtained from a series of measurements made on soil samples collected at the accident site. The measurements were made using a Geiger-Muller counter and a scaler. The results are shown in the table above. The data show that the radioactivity levels in the soil are generally low, with some higher levels in certain areas. The highest levels were found in samples 1, 2, and 3, which were collected from the area immediately adjacent to the accident site. The levels in these samples were approximately 1000 cpm, or 16.7 cps, or 1000 dpm, or 33.3 Bq. The levels in the other samples were generally lower, with most being below 1000 cpm. The data also show that the radioactivity levels in the soil are generally stable over time, with only a few samples showing significant fluctuations. This suggests that the radioactivity in the soil is primarily due to the accident, and is not being significantly affected by other factors. The data also show that the radioactivity levels in the soil are generally higher than those in the surrounding environment, which is consistent with the fact that the accident site is a source of radioactivity. The data also show that the radioactivity levels in the soil are generally higher than those in the surrounding environment, which is consistent with the fact that the accident site is a source of radioactivity. The data also show that the radioactivity levels in the soil are generally higher than those in the surrounding environment, which is consistent with the fact that the accident site is a source of radioactivity.

Table 16

Fluoride concentration in Water Samples Collected at *Boa Vista Island*, 1970-1977

Sample No.	Collection Location	Number of samples	Fluoride, mg/liter	Mean $\pm$ SD

			Aug. '77	1	30.00	7	37	

a. n = sample; the number of samples which were analyzed is the same as n.

b. Total chloride value for three samples (n = 3) is a mean of a sample of 3 of the results. In our system, presence of a sample means the collection of a minimum of three samples. The total amount of chlorine of these individual sample values.

c. Total of sum of the sum of the year.

d. 0.000000 below laboratory level.

e. 116.76 to 200 mg/l appears from Survey Day.

f. 116.76 to 26 mg/l appears from Survey Day.

APPENDIX 2

RESULTS OF PLUTONIUM AND GAMMA  
SPECTRUM ANALYSES OF ENEWETA\*  
PLANT, RAT AND SOIL SAMPLES  
COLLECTED IN MARCH 1956

UNIVERSITY OF WASHINGTON  
LABORATORY OF RADIOISOTOPE PHYSICS  
RESEARCH REPORT NO. 117

January 25, 1978  
A. Neivins

Principle Investigator: Dr. William H. Miller  
Subject: Results of Gamma-ray and Gamma Spectrometry Analyses of  
Mashed Potato, Leaf, and Soil Samples Collected in  
Oregon, 1976

Rat, plant, and soil samples from the 1976/77 study were sent to our laboratory by Dr. Jack G. Smith for conducting the plant and soil analysis. These samples had been directly collected and packaged by the local's group.

The soil samples were analyzed by using 2 x 2 inch standard sample holders and counting for 400 minutes on a 4000 cpm system. The gamma-counting results for soil samples are given in Table 1. The quantity of the individual radionuclides was determined by the amount of the standard sample holder in patches of tissue for gamma-ray analysis. The results of analyses for gamma-emitting radionuclides for rat and plant samples are given in Table 2.

After gamma-counting, the samples for plutonium analysis were spiked with  $^{242}\text{Pu}$  as a standard yield. The laboratory standard method for the determination of plutonium. Finally, plutonium was extracted from the samples, separated, and measured with a standard method for the determination of plutonium. The results of plutonium analysis are shown in Table 3.

## UNCLASSIFIED

From 1946 to 1962 atomic devices were detonated under water, over water, on land or in the atmosphere over the waters of the central Pacific. Most of these tests took place at Bikini and Eniwetok atolls in the Marshall Islands and some at Johnson, Christmas, and Baker Islands further east. The distribution of radionuclides produced by these tests has been studied extensively, especially at Bikini and Eniwetok atolls. The present report is part of a Laboratory of Neutronics Ecology program begun in 1974 and described in a previous report (Ricketts, 1977). The purpose of this study was to determine qualitatively and quantitatively radionuclide presence from certain food sources in areas of Micronesia other than those near nuclear testing localities during the test periods. Areas sampled were Majuro Atoll in the Marshall Islands, Chuuk and Pohnpei in the Caroline Islands, Rongerik in the Mariana Islands and Rongerik and Jaluit in the Line Islands. Data on radionuclide collection in these areas will provide a comparison with the results and trends of radionuclide found in similar samples from Bikini and Eniwetok atolls.

## UNCLASSIFIED

The areas mentioned above were visited in November 1975. In addition to these areas, one other site related with the test sites at Bikini and Eniwetok atolls, white bird colonies 2 and 3 in collection given within these areas, is shown. The study was a joint survey with personnel from Brookhaven National Laboratory (BNL) who took radiological survey readings with sodium iodide (NaI) scintillation detectors and a pressurized ion chamber. The results of the survey readings will be given in a separate BNL report. Personnel from

laboratory collection representative biological soil (all samples with abundance of fungi) from the 1000 m level on the slope near road (1000, 1500, 2000, 2500, 3000, 3500, 4000, 4500, 5000, 5500, 6000, 6500, 7000, 7500, 8000, 8500, 9000, 9500) and from multiple locations of these elevations were also collected and the year 2010 was collected to compare data for estimation of future distribution and quantities of radiocesiums in the environment in India.

The number of samples after division into various elevation fractions, is shown in Table 1. Seventy percent of all samples were biological - plantations, and about 30% - randomly selected soil samples - surface (0-2.5cm) and profile (0-10cm). Approximately equal numbers of samples came from about five major collection zones.

#### ANALYTICAL METHODS

##### Beta-Ray Spectrometry

All of the samples were analyzed by gamma-ray spectrometry - either with a  $20 \times 20$  cm NaI(Tl) crystal (1141mm diameter) crystal and 200-channel pulse-height analyzer or with a germanium (110mm diameter) single detector and 4096-channel, 0.1keV-field analyzer. Soil samples were analyzed on the Ge(Li) system, and the biological samples were analyzed on NaI system.

All samples were oven dried, ground and a portion compressed into sample holders of polyvinyl chloride (PVC) size 2 inches in diameter and either 1.2 or 1.5 cm for radiocesium measurements. Only pieces of tissue or 6 grams of soil could be compressed into the 20 x 20 holder. The densities of the biological and soil samples were 1.0 and 1.25, respectively. These samples were then analyzed for gamma-emitting radionuclides.

The gamma emitting radionuclides by the samples counted on the NaI crystal were determined by a method of peak ratios. The radionuclide values for samples counted on the Ge(Li) detector were calculated either manually or with

Table 1. Distribution of samples collected on the Hawaiian cycle from 1976 to 1980.

- a. The cores given to the total sediment samples have been divided into tissues or fragments of soil depth.
- b. Three cores of coral were also collected on an island south of Kauai. The organic carbon from, and a subsample of 20 or larger, shells were collected and analyzed for <sup>90</sup>Sr and <sup>137</sup>Cs and <sup>240</sup>Pu.

corrected by adding the counts from one or more of the channels above a peak in the spectrum, subtracting the appropriate background counts, and applying correction factors to correct counts to protons ( $p(t) = A \cdot t$ ) of previously counted reference specimens of the type of sample holder and radionuclide measured.  $A_{90}$  values were measured for decay to the date of publication.

#### Counting and Statistical Analysis

For accurate  $^{235}\text{U}$  control,  $^{235}\text{Y}$  was chemically separated from  $^{238}\text{U}$ , collected in a thin cap space and counted with a low level beta counting system. The tracer was extracted by ion exchange, electrodeposited on platinum discs, and counted by alpha spectrometry with system online software for alpha detection and other health analysis. Chemical yield was determined by use of  $^{235}\text{U}$  tracer.

#### Error Limits

For a given sample, the error given for all concentrations listed are based on a standard, counting error. The error term for the mean of less than one sample is one standard deviation (one sigma) counting error.  $\pm 1\sigma$  of detection

Many factors influence the limit of detection, including the type of detector and analyzer, the amount of alpha emitters, the duration of the counting period, the size and density of the sample, and the geometric relationship of the sample and detector. Therefore, limits of detection varied considerably for various radionuclides and types of samples, not can be generalized by stating that detection limits were approximately  $\pm 1\sigma$  of

By gamma detection

$^{137}\text{Cs}$	2.11 $\mu\text{Ci/g (wet wt)}$
$^{90}\text{Sr}$	0.41 $\mu\text{Ci/g (wet wt)}$

By beta detection

$^{90}\text{Sr}$	0.2 $\mu\text{Ci/g (wet wt)}$
------------------	-------------------------------

By alpha detection

$^{238}\text{Pu}$ , $^{239}\text{Pu}$	0.07 $\mu\text{Ci/g (wet wt)}$
---------------------------------------	--------------------------------

#### RESULTS AND DISCUSSION

Data are presented in Appendix Table 2. General 11 for the results of the analyses of the samples collected by net in Michigan in 1975. All fish are given as picograms per gram of dry weight (pg/g, dry), except where expressly noted. Table 2 gives the general relation to dry weight rather than to whole fish weight. Thus the pg/g, dry values may be converted to pg/g, wet for purposes of comparing activity levels of the various radionuclides. There may be greater differences in the radioactivity values between samples of the same collection date (see Table 2), the results will be given in the following types.

#### Fish

Seven species of fish were collected from the immediate vicinity of the Rivermouth, Mich., and  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  were detected. Common blue gill, white perch were collected at large numbers. As shown in Appendix Table 1, activity resulting from  $^{137}\text{Cs}$  was the only measured phenomenon in fish tissues at a concentration greater than 0.6  $\mu\text{Ci/g, dry}$  and the average value was 4.6  $\mu\text{Ci/g, dry}$  (mean = 2.6) was detected in only four of 31 samples. The mean concentration of  $^{90}\text{Sr}$  measured was 0.9  $\mu\text{Ci/g, dry}$  in the viscera of fish from Port Huron.  $^{90}\text{Sr}$  was detected in 1 of 25 tissue samples analyzed.

"  "	(1)	kidney	4.00	

with  $^{238}\text{Pu}$  was not above the limits of detection in any of the eight samples analyzed.

The amount of  $^{239}\text{Pu}$  in these fish was less than the amount reported (Relson, 1977) in fish from Bikini, Rongerik, and Ailingiue atolls. It is not from the Marshall Islands which have low radiation levels, but which can receive some local fallout during the testing of Bikini and Eniwetok. The  $^{239}\text{Pu}$  content of  $^{238}\text{Pu}$  in the two (6 of 8) fish samples which contained  $^{238}\text{Pu}$  in quantities greater than our limit of detection was similar to  $^{239}\text{Pu}$  concentrations in fish from Accordeo Island in the Aitutonga (Relson and Seaman, 1977), and in fish collected from Japanese coastal waters in 1971 and 1972 (UIC, 1976).

The concentrations of  $^{235}\text{Pu}$  and  $^{240}\text{Pu}$  were very low, below the limits of detection in fish samples from the three atolls noted above and in the five samples analyzed for this report.

#### Organic Matter

Three organic acids from crabs were detected and the fusion peaks for analysis. Results of these analyses are shown below in all/g/g dry.

Time	$^{239}\text{Pu}$	$^{238}\text{Pu}$	$^{235}\text{Pu}$	$^{240}\text{Pu}$	$^{87}\text{Sr}$	$^{137}\text{Cs}$
Leucolite	17.0 ± 1.1	2.7 ± 0.85	1.5 ± 0.09	1.7 ± 0.1	0.772	
Diethylamine	45 <sup>B</sup>	95	0.17 ± 0.09	0.25	0.891	
Methyl	61 ± 0.1	10	0.19 ± 0.09	0.23	0.891	

B, not statistically significant

The values for  $^{235}\text{Pu}$  and  $^{240}\text{Pu}$  in these crabs are less by a factor of four than amounts in crabs from Rongerik and Ailingiue atolls and are similar to amounts found in crabs from Eniwetok in Atoll, which did not receive any appreciable local fallout from the testing of the Pacific Test Site.

## Plants

Four species of plants, pandanus, coconuts, bromeliad and plums, were collected from one to three sites on the east of the lagoon using collection methods. In addition bamboo, coconuts, casave were collected at one site. Results of the analysis of these samples are given in Appendix Table 2 through 6.

Radioactive cesium ( $^{137}\text{Cs}$ ) was the most common radionuclide measured in the plant samples. All the island radionuclides, only  $^{137}\text{Cs}$  was detected in any of the 10 percent of the samples. Most values of  $^{137}\text{Cs}$  were less than 1.0 d/g, but a value of 0.8 p/g was measured in the edible portion of coconuts from one site. The edible portion of this fruit also had a high  $^{137}\text{Cs}$  value. 16 plums, 14 more high-accumulated values of  $^{137}\text{Cs}$  were excluded, but  $^{137}\text{Cs}$  values in plants from these are similar to values in plants from Palau and Guam when the data were available. Bananas had slightly higher amounts of  $^{137}\text{Cs}$  in the plants, while plants from Micronesia had the highest average amount of  $^{137}\text{Cs}$  - 7.0 d/g, 60 percent of the  $^{137}\text{Cs}$  value. In the coconuts from Micronesia were about 1.0 d/g - about 100 percent of plants from Guam and similar pattern, while  $^{137}\text{Cs}$  values were about the units of detection in one sample of coconuts from Micronesia and two samples of bromeliad from Guam.

The values for  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  in plants from Guam, Palau, Pohnpei, and Yap were less than values for the same plants from the Marshall Islands (G. van, 1977) but were similar to values from a food plants from Japan (Miy, 1976) and Washington State (Wilson and Seymour, 1976).

## Soil

Soil cores (0.5 m) soil samples at a shallow soil profile were collected from several sites in each district. Results of the analysis of these samples

are presented in Appendix Tables 7 through 9. For 10 of the coastal soils (i.e., 13 sites), generally combined total (s.d. 16.1%) amounts of  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{241}\text{Pu}$  were found. These two volcanic islands of Hawaii, French Frigate Shoals, in addition to other volcanic islands, also contained generally combined average total amount of plutonium. The soil from French Frigate Shoals (Site 10) had 2% in addition to  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{241}\text{Pu}$  (no  $^{242}\text{Pu}$ ), but  $^{242}\text{Pu}$  was absent on the soils from other sites. Relative differences in the amount of  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , or  $^{241}\text{Pu}$  found in the soil samples were related to the two volcanic islands.

Total amount of plutonium isotopes on French Frigate Shoals was higher values on  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{241}\text{Pu}$  than did the soil collected from the other sites, but not from the other districts. For instance, the  $^{238}\text{Pu}$  values from the soil samples there were two orders of magnitude higher than  $^{238}\text{Pu}$  from other districts, and the  $^{241}\text{Pu}$  values were one order of magnitude higher. Less  $^{240}\text{Pu}$  and  $^{242}\text{Pu}$  were not detected in soils from any district other than French Frigate Shoals. The range of values for the plutonium isotopes in soils from the areas as follows:  $^{238}\text{Pu}$  (n = 10),  $^{239}\text{Pu}$  (n = 72),  $^{240}\text{Pu}$  (n = 147),  $^{241}\text{Pu}$  (n = 103), and  $^{242}\text{Pu}$  (n = 16).

Results of the analyses of the soil profiles indicated that the concentration of the total plutonium ( $^{238}\text{Pu}$  and  $^{240}\text{Pu}$ ) decreased with distance with the concentration of the naturally occurring plutonium (i.e.,  $^{244}\text{Pu}$ ) relatively constant up to the depth of one-cm soil samples. Most of the  $^{238}\text{Pu}$  and  $^{240}\text{Pu}$  was present in the top 1 cm of the soil profiles.

Considering only low fallout plutonium sites, low values for  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ , and  $^{240}\text{Pu}$  in soils from French Frigate Shoals are higher than values for these plutonium isotopes in soils from sites in the northwestern United States such as Nevada, Oregon, and California, and are much less than in soils from British Columbia (Johnson, 1977).

## SUMMARY AND CONCLUSIONS

This study of radionuclides in plants, soils, and soil from five sites in Bikini was one part of ERDC Pacific Radiocology Program. The overall purpose of this part of the program is to determine the kinds and amounts of radionuclides in biological and environmental samples from the Central Pacific. The scientific purpose of this study was to measure the radionuclides present in food in Bikini, and soil from areas of Pisonia which did not have appreciable fallout from the tests of Bikini and Eniwetok atolls. Approximately 200 samples from this study were collected during November, 1971, and 200 specimens, 100 stems, 50, and 50 specimens 200, 200 analyzed in the laboratory.

Results of the analyses indicate that radionuclides occurring in  $^{238}\text{Pu}$  in the plants and soil in Bikini. The biological transfer coefficient was found to be highest in the soil, and lowest in the plants. Although plants from Bikini had a relatively greater amount of  $^{238}\text{Pu}$  than plants from the other districts,

soil samples from all districts, mainly contained less than 1.0 pCi/g of  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{241}\text{Pu}$ , which were from soil, below, and by the also contained less than 2.0 pCi/g radionuclides in any form of radionuclides. Soil from Bikini contained the most radionuclides and radionuclides in radionuclides, and in addition contained  $^{238}\text{Pu}$  and  $^{239}\text{Pu}$ . Amounts of the radionuclides occurring in radionuclides in the soil were much higher than amounts of radionuclides occurring in radionuclides from the other districts.

Considering only the fallout radionuclides, the values for  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$ , and  $^{240}\text{Pu}$  in plants and soils from Bikini, Eniwetok, and the other districts were less than values for these radionuclides in soil from samples collected at all such as Eniwetok, Rongerik and Ailinginae in the northern Marshall Islands.

and in Table I are the values of these coefficients for samples from Flint and Longley areas.

## INTRODUCTION

As stated in a previous progress report (Belton, 1977),

"The Division of Operational Safety in 1975 (now Safety Standards and Compliance) portion of the Institute of Radiation Ecology (IRE) in the Radiobiology Program (now the Radiation Atoll Program) began on July 1974 and is conducting the support of this program is to determine the time and amount of fallout loads distributed in the food chain, animals, and soils of the Central Pacific, especially the Marshall Islands, and to furnish this data to MS/1804 and other appropriate agencies (Hawaii, Johnston Atoll, Nevada Operations Office (NO)) so that they may make an assessment of the dose of fallout radiation received by the people living throughout the Central Pacific."

Here we report the results of the analysis of samples collected on a field trip conducted in September-October, 1976.

## SAMPLES THROUGHOUT

Atolls visited in the Marshall Islands are shown in Figure 1. This trip was a joint survey with personnel from the Environmental Laboratory. Representative biological and soil samples were collected with emphasis on food items common to the diet of the Marshallese people (i.e., fish, coconuts, pandanus breadfruit, coconut crab, etc.) - along with inedible portions of these items, were also collected and analyzed. Soils were collected to provide data for estimating future distributions and conditions of radionuclides in the environment and to obtain background information (Figures 2 through 5).

The number of samples collected divided into three soil fractions, as shown in Table 1. Slightly less than half the samples were arthropods, fish, clams, and coconuts (only 1 sample for each was collected) - samples (0-100-um).

Figure 1. Five atolls (underlined) in the northern Marshall Islands where samples were collected September-October 1974.

Island	SAMPLES PROCESSED				SAMPLES ANALYZED		
	Plasma	Urine	Excretion	Spot Urine	Spot Urine	Urine	Plasma
Wotho	20	20	2	20	20	20	20
Ujae	20	20	2	20	20	20	20
Ujae	20	20	2	20	20	20	20
Ujae	20	20	24	20	20	20	20
Ujae	20	20	2	20	20	20	20
<b>Total</b>	<b>100</b>	<b>100</b>	<b>10</b>	<b>100</b>	<b>100</b>	<b>100</b>	<b>100</b>

In addition to the samples currently being collected, personnel from Pennsylvania State University have collected samples under the same conditions and for radiation survey readings with sodium iodide (NaI) scintillation detectors and a gamma-ray spectrometer. The results of the Brookhaven polymer and cement counts may be combined with the FBI results in a series of joint reports to the area literature.

#### ANALYTICAL METHODS

##### High-resolution gamma-ray spectroscopy

All of the samples were analyzed by gamma-ray spectroscopy, either with a 2 x 2 inch sodium iodide (NaI) low crystal crystal and 200 channel pulse-height analyzer or with a germanium (high-resolution) diode detector and 4096 channel multi-channel analyzer. Some samples were analyzed on the NaI(L) system, and the biological samples were analyzed on both systems.

All samples were oven dried, ground and a portion compressed in poly(methyl methacrylate (PMMA) plate 2 inches in diameter and approximately 1/8 inch deep that served as a sample holder for radioisotope measurement. Fifty grams of soil or 100 grams of soil could be compressed into the 2 x 2 inch container. The densities of the biological samples were 1.0 and 1.35, respectively. Some samples were then analyzed for gamma emitting radionuclides.

The gamma emitting radionuclides in samples counted on the NaI counts were determined by a set of 61 channels. The radionuclides values for samples counted on the Ge(Li) detector were calculated manually or with a computer by adding the counts for an energy range of five channels, using a peak in the spectrum, subtracting the appropriate background counts, and applying correction factors to convert counts to picocuries (pCi). A set of previously reviewed reference spectra for the different geometries and sodium iodide crystals used. All values were corrected for decay to the date of collection.

### Strontium-90 and Plutonium Analyses

To measure  $^{90}\text{Sr}$  content,  $^{90}\text{Y}$  was chemically separated from  $^{90}\text{Sr}$ , collected on a filter paper and counted with a low level beta counting system. The filter was extracted by ion exchange chromatation on platinum cases, and analyzed by alpha spectrometry with a system using an ionization chamber for alpha detection and pulse height analyzer. Chemical yield was determined by use of  $^{90}\text{Sr}$  tracer.

### Error Limits

For a single sample, the error given for all radionuclides listed here includes counting and sampling errors. The error given for more than one sample is one standard deviation and disregards sampling error.

### Limits of Detection

Many factors influence the limit of detection, including the type of detector and analyzer, the presence of other radionuclides, the duration of the counting period, the size and density of the sample, and the peculiar relationship of the sample and detector. Hence, the limits of detection are not identical for various radionuclides and types of samples, but can be summarized by stating that the detection limits were approximately as follows:

By gamma detection

$^{90}\text{Sr}$	7.1 $\mu\text{Ci/g}$ or less
$^{90}\text{Y}$	0.61 " " "
$^{238}\text{Co}$ , $^{238}\text{Pu}$ , $^{238}\text{Os}$ , $^{238}\text{Th}$ , $^{238}\text{U}$	0.07 $\mu\text{Ci/g}$ or less

By beta detection

$^{90}\text{Sr}$	0.7 $\mu\text{Ci/g}$ or less
------------------	------------------------------

By alpha detection

$^{238}\text{Pu}$ , $^{238}\text{U}$	0.02 $\mu\text{Ci/g}$ or less
--------------------------------------	-------------------------------

### Table 15

Data are presented for the results of the analyses of the samples collected by RV in the Marshall Islands in 1976. Appendix Table 17 through 19 give the data for single samples. The data are first presented with by atoll and then summarized by comparison between atolls for selected sample types. All data are given as micromoles per gram of dry weight except where expressly noted.

#### Atoll and Major Atoms

Samples from Rongerik and Alikak Islands on Bikini Atoll and from Wotje and Keroke Islands on the Ujae Atoll were collected during the September-October 1976 field trip. Results of the analyses of these samples of fish, plants and soil for gross alpha radioactivity,  $^{238}\text{U}$  and  $^{235}\text{U}$ / $^{238}\text{U}$  are given in Appendix Tables 1 (fish), 2 and 3 (plants) and 4 through 7 (soil).

In the Ujae, naturally occurring  $^{40}\text{K}$  was the most abundant radionuclide. Except for a small amount of  $^{137}\text{Cs}$  in soil and plants, no fallout radionuclides were detected in any of the other food samples. In plants,  $^{40}\text{K}$  was also the most abundant radionuclide, however,  $^{137}\text{Cs}$  was above the limits of detection in all plant samples and  $^{238}\text{U}$  was measurable in about one third of the samples analyzed. Of the plants sampled, pandanus fruit was the most  $^{137}\text{Cs}$  and  $^{238}\text{U}$  enriched material found, but the most  $^{137}\text{Cs}$ . When using the average of tubers for food reserves most of the  $^{137}\text{Cs}$ .

As in Table 17 was the predominant radionuclide in the soil samples from Wotje and Alikak atolls, but the amount measured was less than 1  $\mu\text{Ci/g}$  in all samples except four from Keroke Island, and we therefore have sampling locations on these two

Atoll). Generally, flows of  $^{137}\text{Cs}$  in these four samples ranged from 1.1 to 1.8  $\mu\text{Ci/g}$ . Strontium-90 and  $^{238}\text{Pu}$ ,  $^{239}\text{Pu}$  were measurable in the samples analyzed. Correlations were low. From a procedure on all samples but one, the surface soil from site 3 on Bikini Island. Soil at this site contained 0.8  $\mu\text{Ci/g}$  of  $^{137}\text{Cs}$  per gram. Uranium-235 was detected in only a few of the soil samples.

#### Appendix A-10

The two predominant radionuclides in plant samples from Bikini Atoll were  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  (Appendix table B). Of about 100 samples analyzed, the edible portion of the three dominant food staples contained the greatest amount of  $^{137}\text{Cs}$  (average 14  $\mu\text{Ci/g}$ ). Values of  $^{90}\text{Sr}$  in the plants ranged up to 2.1  $\mu\text{Ci/g}$ . Plutonium-238,  $^{239}\text{Pu}$  values were below the limits of detection in the five plant samples analyzed.

Soil samples from Bikini Atoll contained  $^{137}\text{Cs}$ ,  $^{90}\text{Sr}$ , and  $^{238}\text{Pu}$  in the majority of the samples analyzed for these radionuclides (Appendix table C). Uranium-235 and  $^{238}\text{Pu}$  were also detected in many of the samples analyzed. Earthworm values ranged up to 0.3  $\mu\text{Ci/g}$  and averaged about 0.2  $\mu\text{Ci/g}$  in the two surface soil samples. Some samples from 10 cm below the surface contained 1.11  $\mu\text{Ci/g}$  of  $^{137}\text{Cs}$  per gram. In the surface samples analyzed,  $^{90}\text{Sr}$  values ranged from 0.6 to 3.2  $\mu\text{Ci/g}$  while  $^{238}\text{Pu}$  values ranged from 0.00 to 0.005  $\mu\text{Ci/g}$ . Among the  $^{235}\text{U}$  and  $^{238}\text{U}$  values were less than 0.1  $\mu\text{Ci/g}$ .

#### Appendix A-11

Marine samples of seaweed, coral, fish and shellfish contained  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  in the predominant radionuclides (Appendix table D). Cobalt-60 was also detected in the  $\mu\text{Ci/g}$  amounts, except in the 20 cm deep clam fishery which contained 7.8 to 10  $\mu\text{Ci/g}$ . Samples of suspended organisms also contained  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  with  $^{137}\text{Cs}$  the predominant radionuclide in the plants (Appendix table E).  $^{137}\text{Cs}$  in the coral samples (Appendix table F). Most plant samples contained

to 170  $\mu\text{Ci}$  of  $^{137}\text{Cs}$  per gram of dry tissue, however, several soil samples contained up to 360  $\mu\text{Ci/g}$ . The concentration of the radionuclide was contained 15 to 360  $\mu\text{Ci}$  in 250g soil samples. The other radionuclides contained 1 to 20  $\mu\text{Ci/g}$  (Table 14). The analysis of the soil samples are given in Appendix Tables 14 through 17. Cesium-137 and  $^{90}\text{Sr}$  are the predominant radionuclides with  $^{137}\text{Cs}$ ,  $^{134}\text{Cs}$ ,  $^{90}\text{Sr}$ ,  $^{238}\text{Pu}$  and  $^{239}\text{Pu}$  were not detected in any of the samples analyzed. The following table gives the  $\text{pH}$  values. Antimony 125 was also present in the soils from Rongelap Island. Radiochemical values were listed on logarithmic scale in Appendix Tables and reported on Rn-137 and  $^{90}\text{Sr}$  values for surface soils from where even good several  $\mu\text{Ci/g}$  and ranged up to 200 and 400  $\mu\text{Ci/g}$  for  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$ , respectively. Cesium-137 values in soil from Rongelap Island were less than a hundred  $\mu\text{Ci/g}$ . Plutonium-239 and  $^{238}\text{Pu}$  values in Rongelap and Rongerik island soils were commonly 1 to 10  $\mu\text{Ci/g}$ , while in Rongelap soils values for these radionuclides ranged to 65  $\mu\text{Ci/g}$ .

#### 11.1.4. Algae

Plants were the only source type collected at Rongerik Atoll. Results of the analysis of their samples are in Appendix Table 18. Cesium-137 and  $^{90}\text{Sr}$  are the predominant radionuclides. The greatest  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  values were in the leaves of the poisonous leaves from a noxious plant near 98° 59' E (Figure 2). It contained 2500  $\mu\text{Ci}$  of  $^{137}\text{Cs}$  per gram while leaves from a plant near base of lagoon contained 400  $\mu\text{Ci}$  of  $^{137}\text{Cs}$  per gram. Plutonium 239, 240 and  $^{238}\text{Pu}$  were analyzed but their analysis of detection.

### 11.1.5. MINERAL AND ORGANIC

#### Organic matter, Algae

Flowing in a northeasterly direction, radioactivity values were least in the samples from ledge 200P, increased slightly at Ledge Atoll and increased significantly at Ledge 1. From 100P to Ledge radioactivity values increased to the west.

Thus, long life, *Albani* had higher values than *Albani* and *Albani* for the majority of any anti-radiation during this survey. This pattern has been reported previously (Reison, 1977) and is a result of the latitude distribution for the March 1966 survey from *Albani* to the south to north. Increase in latitude activity is also apparent at *Albani* where the southern islands have radioactivity levels about a factor of ten lower than the northern islands. Significant differences are indicated by:

As noted previously (Reison, 1977)  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  are the predominant radionuclides in biological and soil samples from the terrestrial environment. In addition,  $^{137}\text{Ba}$  and  $^{134}\text{mBa}$  are increasing in activity from *Albani* to the south (Reison, 1977). Because of the quantity of these radionuclides and because they are gamma emitters, which have a higher potential health hazard than many of the alpha emitters, numerous efforts continue to monitor the distribution of these  $^{137}\text{Cs}$  because they concentrate  $^{137}\text{Cs}$  and are abundant and available throughout the year. These efforts may also be used as an indicator for  $^{137}\text{Cs}$  concentration and availability. The existence of these radionuclides were  $^{137}\text{Cs}$  than any other biological sample analyzed. However, these areas are often devoid of vegetation and are populated by birds.

In the marine environment  $^{137}\text{Cs}$  is the predominant radionuclide. *Albani* was the only island radionuclide present in a significant number of the samples analyzed and the relative radioactivity was usually less than 1% of the activity of the *Albani* had the species means of 5% of the marine samples analyzed.

## DISCUSSION

The monitoring of the  $^{137}\text{Cs}$  radioecology Program began on 1 July 1976. The purpose of this program is to determine the types and amounts of radionuclides in biological and environmental samples from the Central Pacific

especially the Hawaiian Islands. A field study was conducted for this purpose in September-October 1976. About 1000 samples were collected and about 200 analyzed. 130 samples for Sr and Zr plants, 220, 240 and 260 for plants, and 200 for plants.

Results of the analyses indicate that  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  are predominant in the terrestrial environment and, in particular,  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  are also reported in the soft-tissue of the *Arctostaphylos*.  $^{137}\text{Cs}$  is the predominant radioisotope in the marine organisms, with  $^{137}\text{Cs}$  being present in the majority of the *Lythrum* plants.

Amounts of radioactivity between islands and between islands within the Hawaiian Archipelago vary with distance from the lava flow at Kilauea Iki and in relation to the fallout pattern from the March 1964 H-bomb test. Plants from Kilauea Iki had the highest amounts of radioactivity, followed by  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  plants from Kilauea Iki and from the Hawaiian Archipelago. The southern islands of the Hawaiian Archipelago and the Hawaiian Islands had the lowest amounts of radioactivity, while Kilauea Iki and the Hawaiian Islands had the lowest amounts of radioactivity of the archipelago during the 1964 test.

	103013	0.11	0.77	0.31
	103014	0.11	0.77	0.31

1. The error of 20% for the radionuclide concentration is based on the standard deviation of the mean for each sample.

2. The error of 20% for the net sample count is based on the Poisson distribution. The error of 20% for the net sample count is based on the Poisson distribution.

APPENDIX TABLE 1  
 Lead and cadmium in soil collected on Ulithi Island,  
 Marsh Area, September 1976

Widened	0-2.5	nd	1.0-0.11	nd	200-300	1.5-2.0

1. The error values for <sup>210</sup>Pb and <sup>210</sup>Po activities are low counts, propagated, counting error of  $\pm 10\%$  or more.

2. nd = not significant; the net sample count is less than the low count propagated counting error.

APPENDIX X (TABLE 10)  
 Summary of Data of Gamma-ray Soil and Sediment at Bikini Atoll  
 September, 1966

a. The error values for all radioisotopes are two sigma, presumed, and from radioactivity sample.

b. ns is not significantly different sample from background from the two sigma properties counting error.

1. The only plant species listed and analyzed, Scaevola, was found growing in a single stand.

2. The only radionuclides detected in the samples listed in this Appendix were cesium-137 and cesium-134. The cesium-134 was detected in only one sample.

APPENDIX E

GAMMA EMITTING RADIONUCLIDES IN  
PLANTS AND SOIL SAMPLES COLLECTED  
AT BIKINI ISLAND IN OCTOBER 1977 AND 1974-1976

## Gamma Emission Spectrometry of Gamma-ray Soft Samples

Collected at Bikini Island in October 1977 and 1974-76

A field trip to Bikini Island for the purpose of 1977 was cancelled because of the unavailability of the support ship, the *Intrepid*. However, a collection of samples was made in October 1977 as part of a larger program, the Laboratory's "Ecogeochemistry of the Pacific Islands" supported by the Division of Biomedical and Environmental Research. This collection was for a routine available basis and therefore was not as intensive as planned for the original field trip but some of the samples were collected as water samples, which had been collected in 1974, 1975 or 1976. Following is the description of the gamma emitting radionuclides in the October 1977 Bikini Island samples and also, for the purpose of comparison, the results of analysis of similar samples collected in previous years.

The locations of the sites of Bikini Island where samples were collected in October 1977 are shown in Figure 1. The gamma emitting radionuclide  $^{137}\text{Cs}$  is  $> 10^4$  and the results of analysis of this radionuclide in 33 samples from edible plants (coconut, pandanus, breadfruit, papaya) are presented in Table 1 and in Figure 2. The values range from  $0.5 \times 10^4$  to  $4.7 \times 10^4$  dpm per gram of dry sample, with 10 of the 33 samples having the results of analysis for  $^{137}\text{Cs}$  in samples collected from the same collection site in either 1974, 1975 or 1976. A percent of the data in Table 1 are shown to indicate no strong net trend for 1976 in these samples for the 1974-1976 period. In fact, many of the 1977 values are greater than those for earlier years. However, the differences between years for the 6 years probably are not statistically significant because the values in Table 1 are single sample counts and the sample may not have been collected from the same area or from a type of samples in other years.

Soil profile samples were collected at locations 11A, 12B and 11X, in October 1977 and the results of analysis of  $^{137}\text{Cs}$  in samples for 1976, 1974, 1975 and 1976 are given in Table 2. The standard confidence line was  $1.0 \times 10^4$  and the radionuclide of source given in database was  $^{137}\text{Cs}$ . Also presented in Table 2 are the results of analyses of soil profile samples collected at 11A, 11B in 1974. The 1977 values appear to be greater than the 1974 values for several of the soil profiles and the difference may not be statistically significant.

The data for  $^{137}\text{Cs}$  in soil profile samples from 11A, 11B for 1977 and 1974 are shown graphically in Figure 3. For samples 11A and 11B, the 1977 values are distinctly greater than the 1974 values which would indicate an increase in  $^{137}\text{Cs}$  in the soil profile during the period. The ratio of the concentration of  $^{137}\text{Cs}$  with respect to  $^{137}\text{Cs}$  in the soil profile expanded from the values at the surface and at 4 cm being  $10^4$  and  $7 \times 10^4$  dpm per gram of dry sample, respectively, to  $1.5 \times 10^4$  and  $1.7 \times 10^4$  dpm per gram of dry sample, respectively, as shown in Figure 3 and 4. Values for potassium and calcium in samples collected at the 11A, 11B (1974) and the soil profile samples for the soil profile were  $1.7 \times 10^4$  and  $1.7 \times 10^4$  per cent of dry sample and the radionuclide of potassium collected in October 1977.

The 1977 national tide was reported to be significantly greater at sites 2, K and C and at holes 24 and 35 (all row 25-26) in recent years. For this reason, the persons collecting the samples were asked about the opportunity to collect samples in 1977 that conflicted with samples collected in recent years. Pit 9 was positively identified but the location of the pit from which samples had been collected earlier could not be described because of ploughing. Pit 10 was dug in a de-ice run in the ground but there was no positive identification that this was the former site of pit 10. Pit 11 was a trench that could not be located. As a result the remaining pits that were sampled in 1975 could not be positively identified as there were several candidates on the beach. At hole 21, the trench could not be found but the person who had buried the house that was sampled in 1977 was probably the one that had been dug. At hole 25, row 35, the trench could not be found and the hole sampled was one of three that was present. Therefore, because of the uncertainty in obtaining duplicate samples, some caution in the estimate of the difference in radionuclide values between years has been taken.

Table 1. Cesium-137 values for plants collected on Bikini Island in October 1977 and for similar samples collected between 1974 and 1976.

## Interlaboratory Comparison Program for Radioisotope Detection Limits

Since 1971, the laboratory has participated extensively in interlaboratory comparison programs to measure the detection limits of "unknown" radionuclides in both standard and environmental sample media. From these results and from the results of routine analysis of duplicate standard sample media, we have corrected and improved our methods and detection limits. We have established and maintained the quality of our analytical work.

For the interlaboratory programs we have analyzed about 170 samples including about 70 various type specimens. Our current programs are with the International Atomic Energy Agency (IAEA), the Environmental Protection Agency (EPA) and the Environmental Measurements Laboratory (EML) (formerly the Health and Safety Laboratory (HSL)). For IAEA, about 100 samples are analyzed yearly; for EPA, mostly fresh water and fish samples quarterly; and for EML, samples of fresh water, sea water, river sediments, marine sediments, fish meal, vegetation meal, and soil are analyzed quarterly.

The results of our analysis and of all other laboratories participating in these programs have been tabulated and a report prepared of the tabulation, "Summary of Quarterly Data of Results of Radioisotope Analysis". The report was prepared by Mr. W. A. Howell (August 1972) and is available upon request. Generally, our results have compared favorably with known values in the standards and with the mean values for all laboratories for the "unknown" radionuclides in the environmental samples.

The methods of analysis used for the interlaboratory program and commonly used in our laboratory for the analysis of other materials are as follows:

1. alpha emitting radionuclides - standard methods for  $^{210}\text{Po}$ ,  $^{210}\text{Pb}$ ,  $^{210}\text{Bi}$ ,  $^{210}\text{At}$ , and  $^{210}\text{Fr}$ ; zinc sulfide scintillation tube counting for general alpha measurements.
2. beta emitting radionuclides - chemical separation and counting for  $^{90}\text{Sr}$  and  $^{137}\text{I}$ ; liquid scintillation methods for  $^{90}\text{Sr}$  and low background, gas counting methods for most beta emitters.
3. gamma emitting radionuclides -  $\text{NaI}(\text{Tl})$  or  $\text{NaI}(\text{Cl})$  detection systems for radionuclides such as  $^{226}\text{Ra}$ ,  $^{228}\text{Ac}$ ,  $^{228}\text{Th}$ ,  $^{228}\text{Pa}$ ,  $^{228}\text{Ac}$ ,  $^{228}\text{Th}$ ,  $^{228}\text{Ra}$ ,  $^{228}\text{Ac}$ ,  $^{228}\text{Th}$ ,  $^{228}\text{Pa}$ , etc.; for x-ray emitters such as  $^{241}\text{Am}$ , chemical separation and proportional counting.

The limits of detection for these systems are important since they govern the amount of a radionuclide that can be considered to be present in a sample. Many factors influence the limit of detection, including the type of detector and analyzer, the presence of other radionuclides, the duration of the counting period, the size and density of the sample, and the geometry relationship of the sample and detector. Hence, the actual limits of detection can vary considerably for various radionuclides and types of samples, but can be summarized by stating that the detection limits are approximately as follows:

By gamma detection:

$^{137}\text{Cs}$	2.1 $\mu\text{Ci/g}$ or less
$^{90}\text{Sr}$ , $^{106}\text{Ru}$ , $^{109}\text{Cd}$ , $^{134}\text{Cs}$ , $^{228}\text{Ac}$ , $^{228}\text{Th}$ , $^{228}\text{Ra}$	0.21 " "
$^{91}\text{Nb}$ , $^{93}\text{Zr}$ , $^{102}\text{Mo}$ , $^{107}\text{Pd}$ , $^{114}\text{mIn}$ , $^{224}\text{Ra}$	0.22 " "

By beta detection:

$^3\text{H}$	6.7 $\mu\text{Ci/liter}$ or less
$^{90}\text{Sr}$	0.2 $\mu\text{Ci/g}$ or less

By X-ray detection:

$^{57}\text{Fe}$	0.04 " "
------------------	----------

By alpha detection:

$^{238}\text{Pu}$ , $^{239}\text{Pu}$	0.02 " "
---------------------------------------	----------
